### Row-stores vs. Col-Stores: How Different Are They Really?

Are column-stores really novel?

If we profile their performance, what is the breakdown? Why?

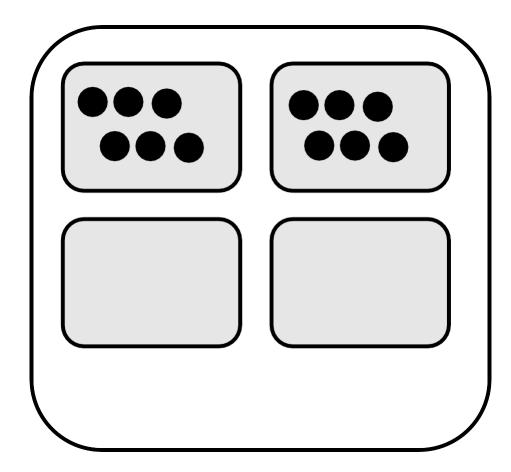

### **Row-Stores**

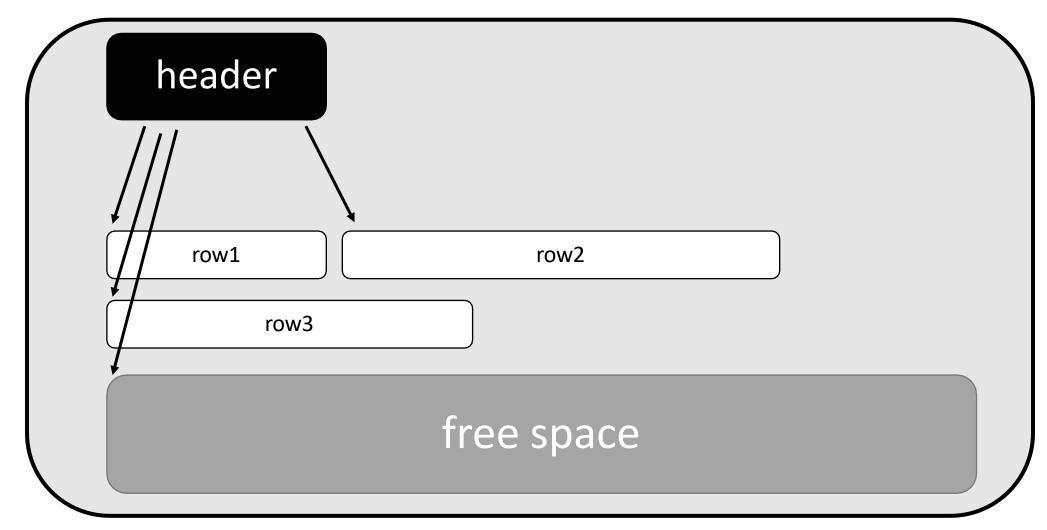

Student (**sid**: string, **name**: string, **login**: string, **year\_birth**: integer, **gpa**: real)

### student

(sid1, name1, login1, year1, gpa1) (sid2, name2, login2, year2, gpa2) (sid3, name3, login3, year3, gpa3) (sid4, name4, login4, year4, gpa4) (sid5, name5, login5, year5, gpa5) (sid6, name6, login6, year6, gpa6) (sid7, name7, login7, year7, gpa7) (sid8, name8, login8, year8, gpa8) (sid9, name9, login9, year9, gpa9)

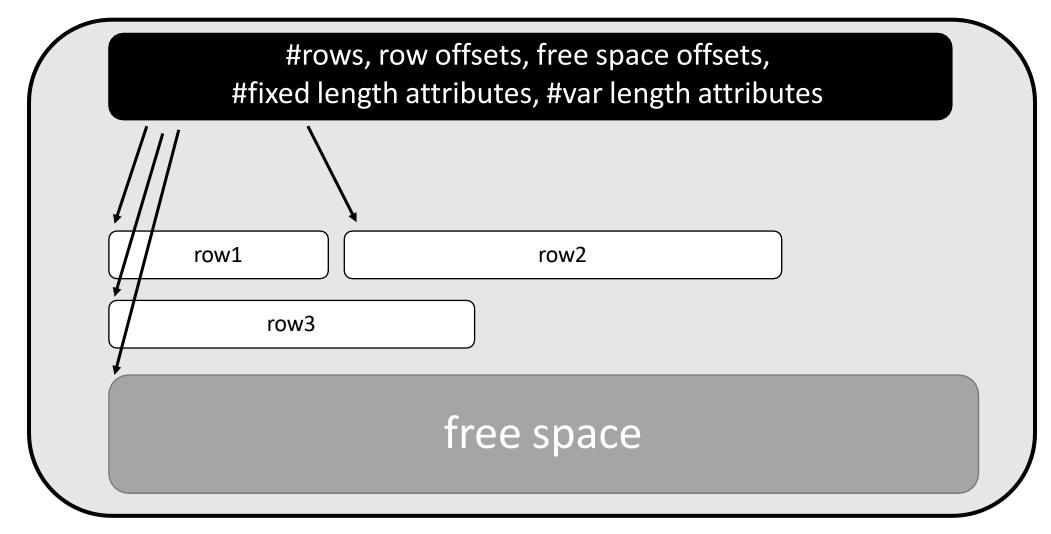

### Row-Stores: slotted page

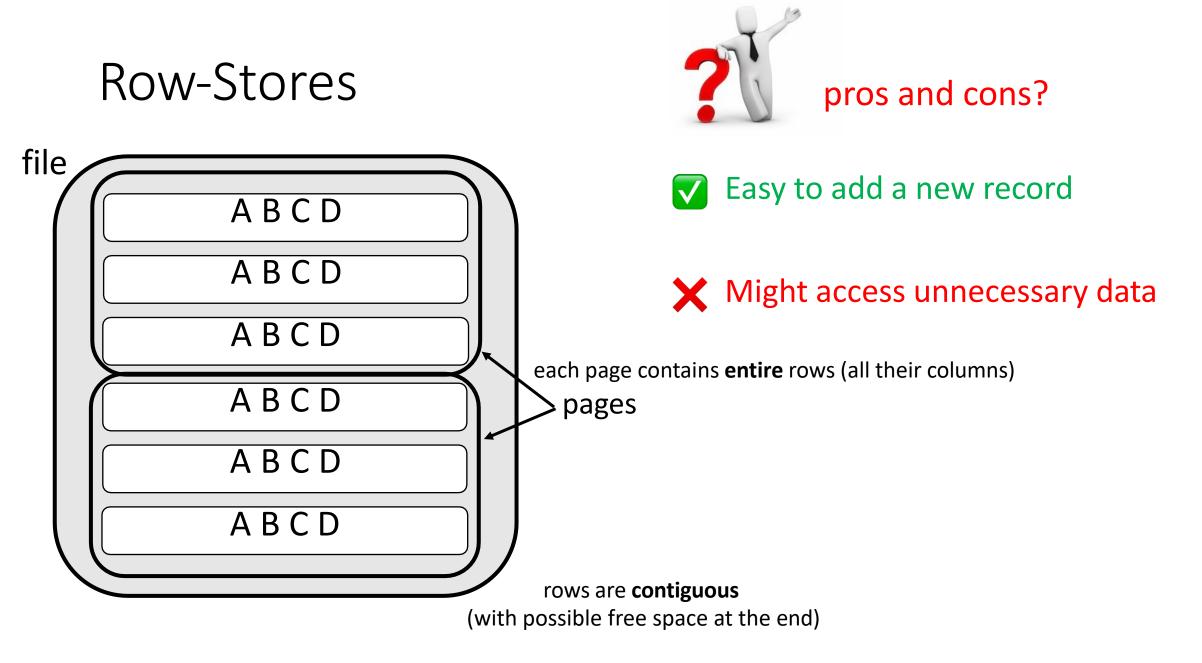

## Row-Stores: slotted page

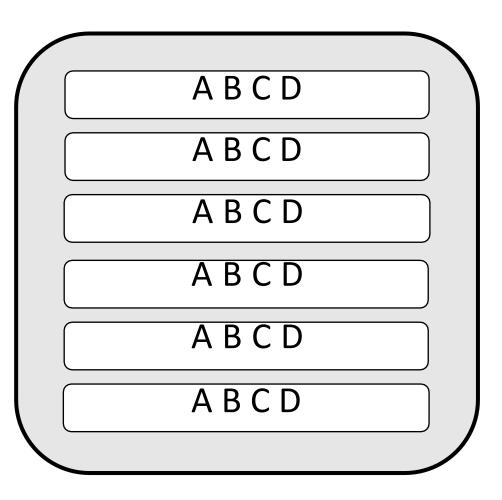

### Row-stores: query processing

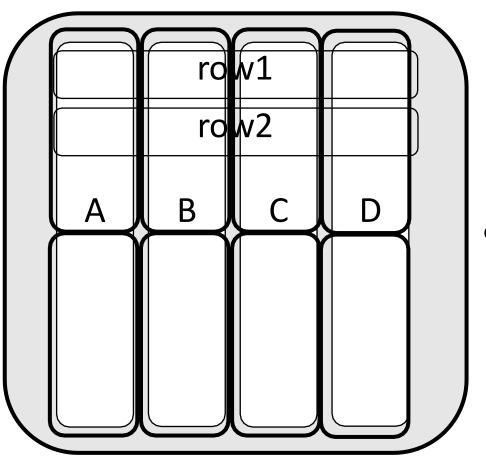

select max(B) from R where A>5 and C<10</pre>

#### ABCD

#### one row at a time

## Column-Stores

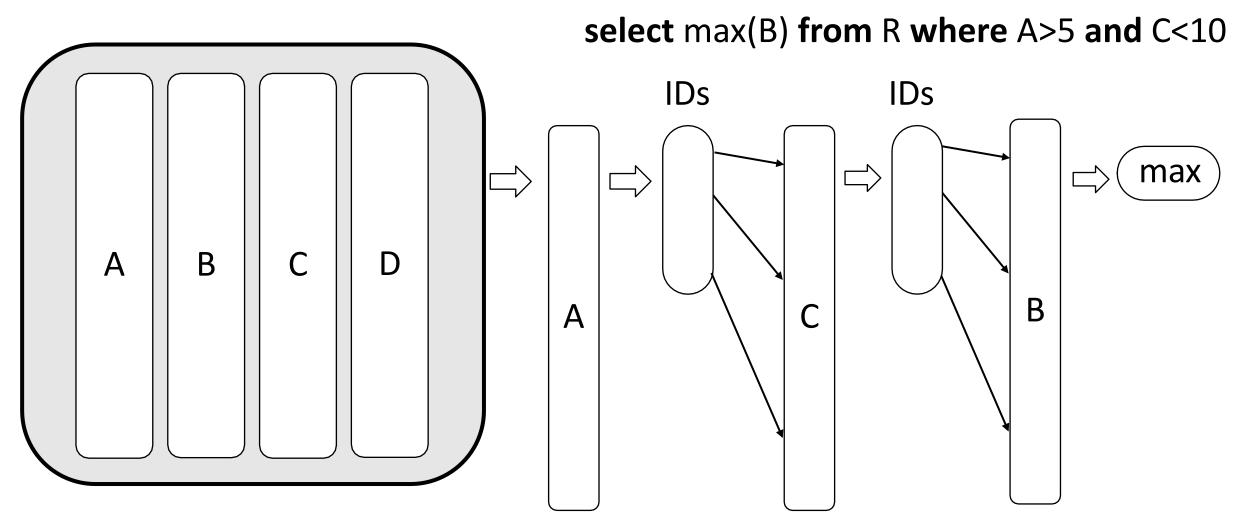

### X Tuple writes require multiple accesses

each page contains columns!

### Column-stores: query processing

#### Let's revisit the main question

There several studies showing

column-stores outperforming row-stores (~5x better performance in TPCH) especially for

read-mostly data warehouses that have

1. column scans and aggregations

2. few and batched writes

Key question:

(a) are the benefits inherent to the new column-store design, or
(b) a row-store with a "more columnar" physical design can achieve the same?
In other words: can you "simulate a col-store in a row-store?"

## State-of-the-art Col-Store features

Late Materialization

"stich the column together as late as possible"

Block iteration

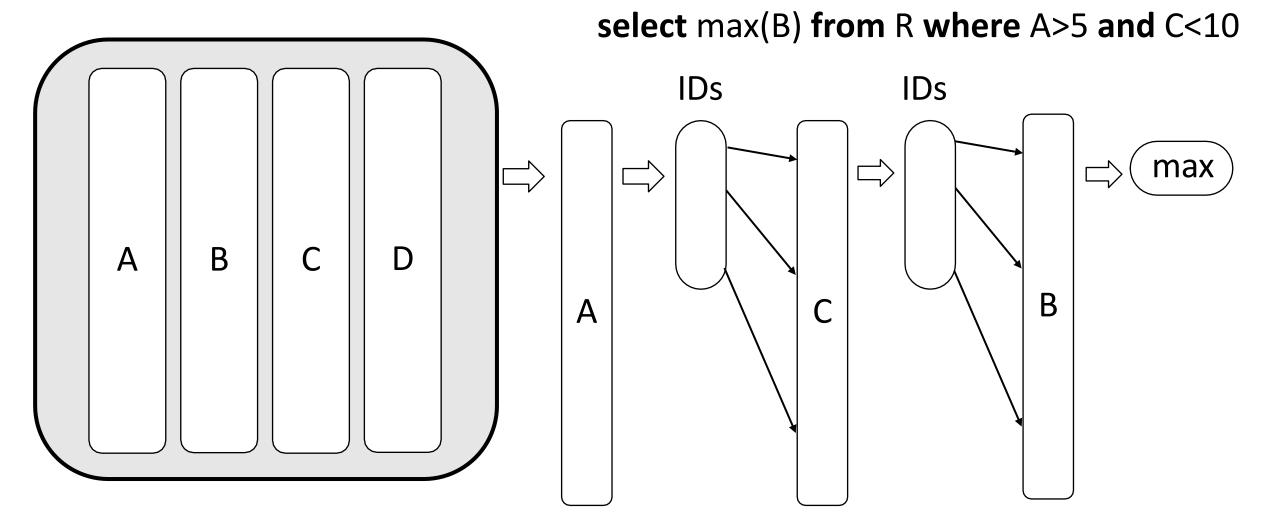

"execute the same columnar operation over a block of values"

Compression

"column-specific compression, due to the nature of data"

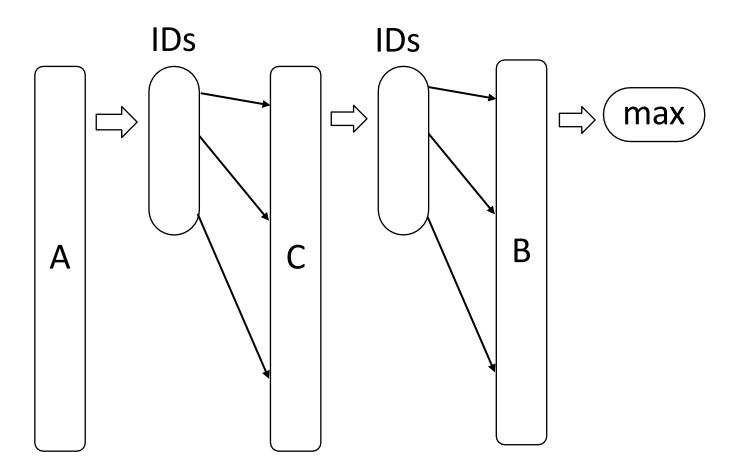

### Late Materialization

"the full tuple (or the necessary subset) is not materialized until it is needed"

# "Column-at-a-time" select max(B) from R where A>5 and C<10

whole column?

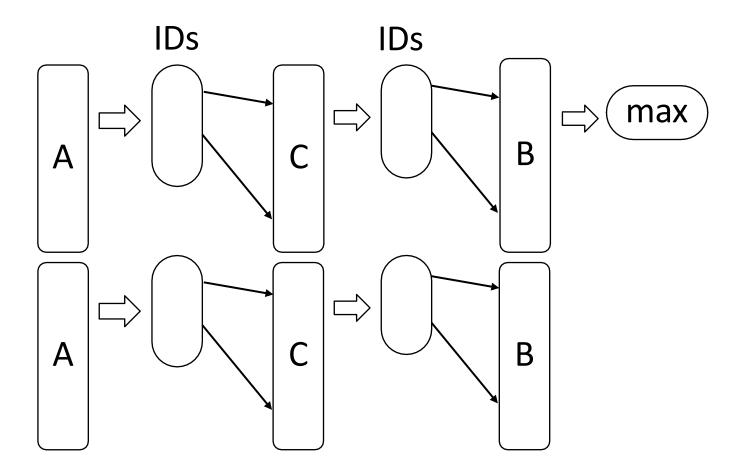

column at a time

block/vector at a time

## **Block Iteration**

#### select max(B) from R where A>5 and C<10</pre>

#### whole column?

column at a time

block/vector at a time

### What is easier to compress?

#1, John, 2/4/88, Boston

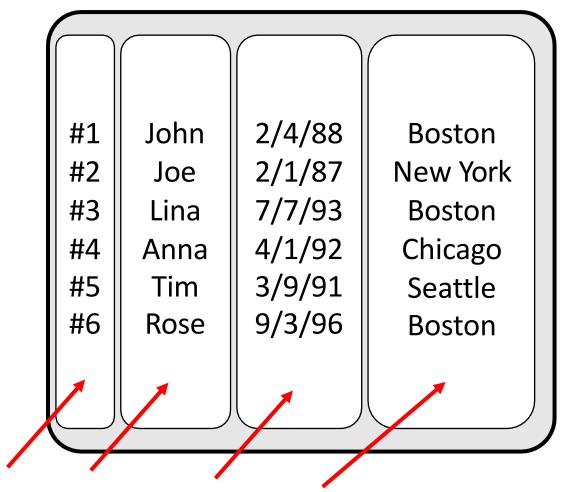

#2, Joe, 2/1/87, New York

#3, Lina, 7/7/93, Boston

#4, Anna, 4/1/92, Chicago

#5, Tim, 3/9/91, Seattle

#6, Rose, 9/3/96, Boston

exploit patterns, duplicates, small differences

## How to simulate a col-store with a row-store?

**Vertical Partitioning** 

"physically partition the data per column"

**Index-only Plans** 

"use only indexes in query plans that contain only relevant columns"

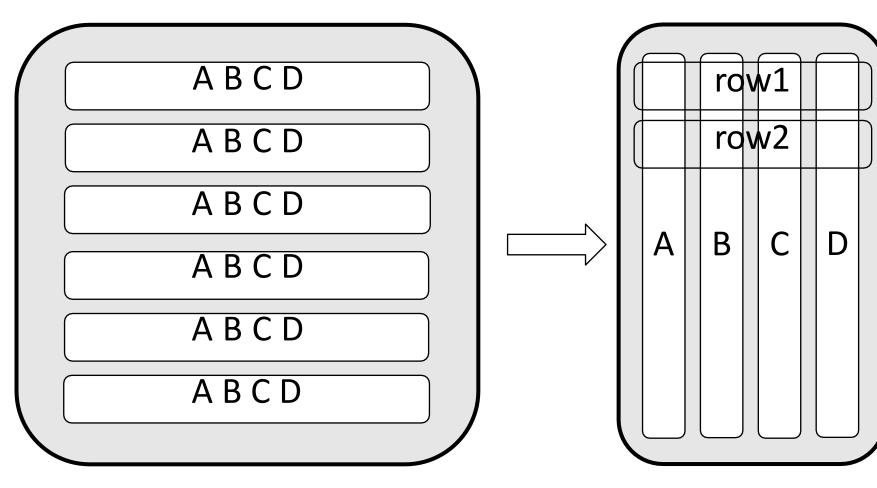

Materialized Views

"temporary tables that contain exactly the answer to a query"

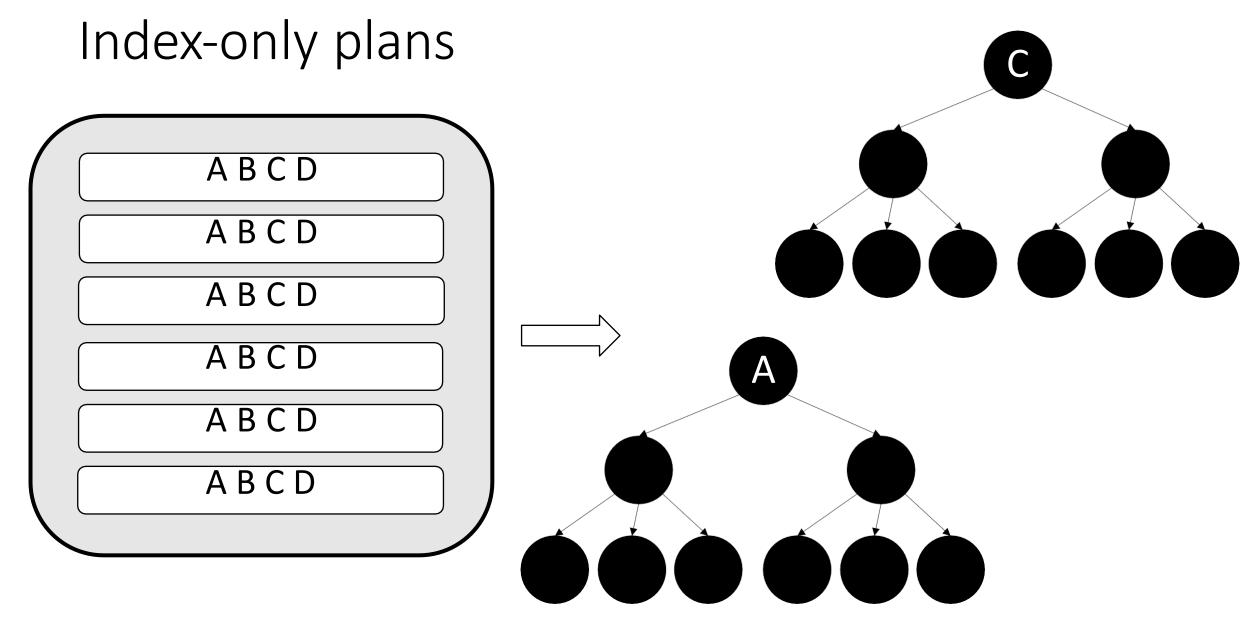

## Vertical Partitioning

select max(B) from R where A>5 and C<10

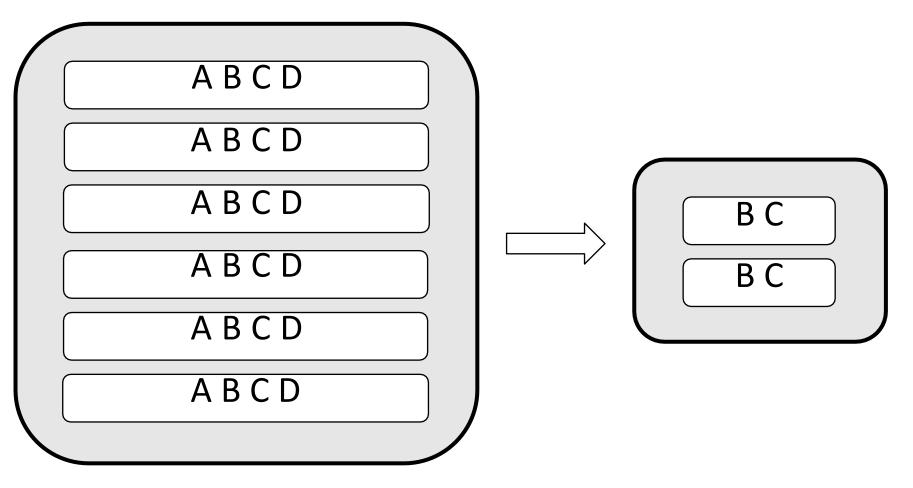

#### select max(B) from R where A>5 and C<10

U SCHOOL OF COMPUTING

### Materialized Views

#### select B, C from R where A>5 and C<10

## Benchmarking

When comparing database systems we need a common "language"

### Benchmarks from the *Transaction Performance Council TPC-B, TPC-C, TPC-H, TPC-DS etc*

Also, a benchmark for data warehousing: Star Schema Benchmark

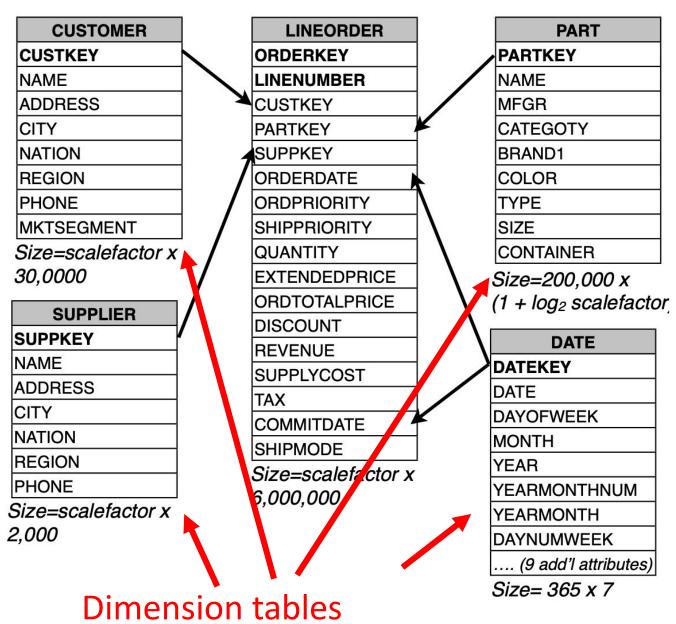

#### Fact table

## Star-Schema Benchmark

#### **13 queries**

```
select sum(lo_revenue), d_year, p_brand1
from lineorder, date, part, supplier
where lo_orderdate = d_datekey and
            lo_partkey = p_partkey and
            lo_suppkey = s_suppkey and
            p_category = 'MFGR#12' and
            s_region = 'AMERICA'
group by d_year, p_brand1
order by d_year, p_brand1;
```

### Experiments

1 CPU 2.8GHz, 3GB RAM, Red Hat Linux 5

4-disk HDD array with 160-200MB/s aggregate bandwidth

(older paper, so small numbers!)

Report averages with "warm" bufferpool (smaller than data size)

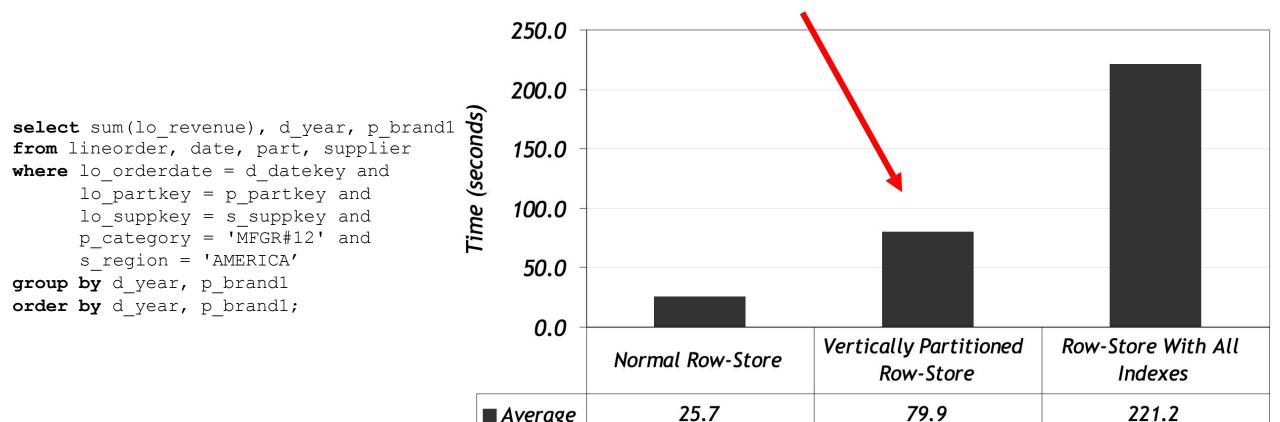

Focus on SSB averages (the paper has more detailed graphs)

## Experimenting with row-stores (SSB averages)

### tuple overheads (additional record IDs)

+ could not horizontally partition + more expensive hash joins

## Details on Vertical Partitioning

TID	Column Data	Т	D	Column Data
1		1		
2		2		
3		3		

Tuple Header	TID	Column Data
	1	
	2	
	3	

Complete fact table 4GB (compressed)

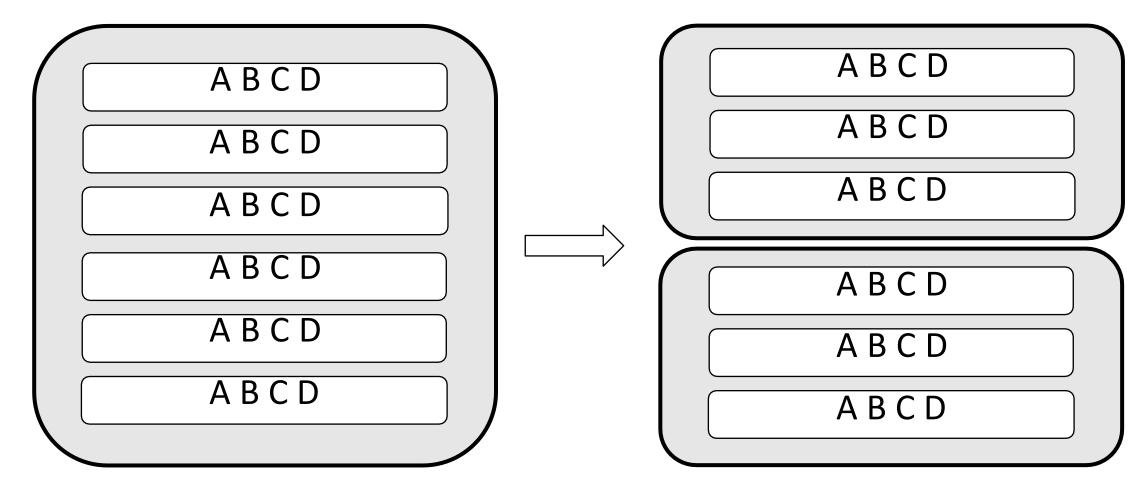

Vertical partitioned tables are 0.7-1.1GB per column (compressed)

Note that a "real column-store" would only store the raw values as an array. In this example it would be only 240MB.

Vertical Partitioning Interferes With Horizontal Partitioning

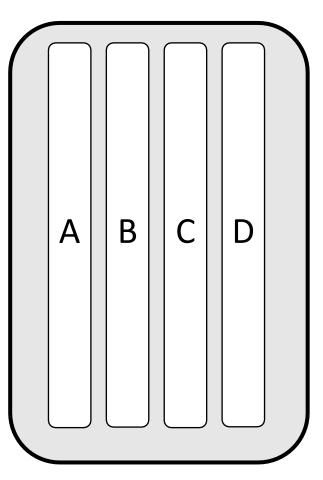

The fact table is horizontally partitioned (on date, allows to skip lots of data)

Vertical Partitioning Interferes With Horizontal Partitioning

The fact table is horizontally partitioned (on date, allows to skip lots of data)

Cannot horizontally partition because the vertical partitions do not contain date info

## Experimenting with row-stores (SSB averages)

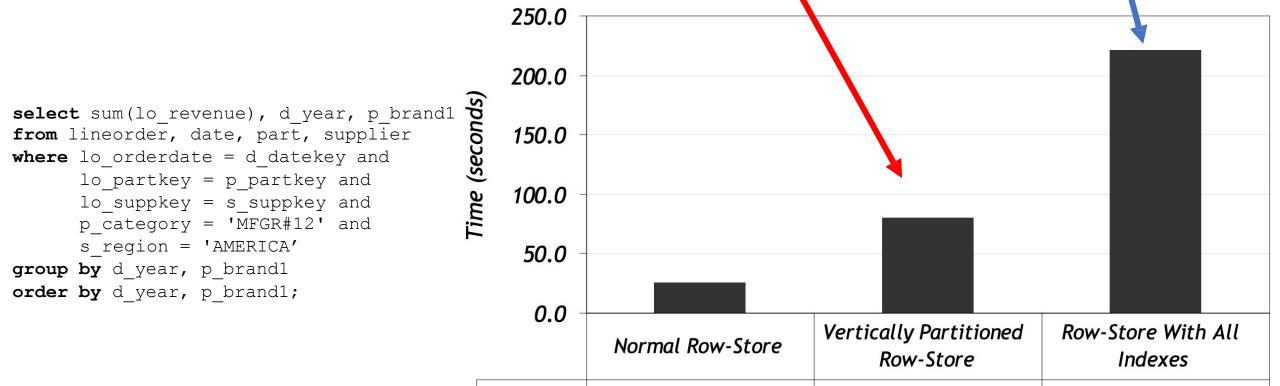

tuple reconstruction (via expensive joins)

79.9

221.2

tuple overheads (additional record IDs) prior to the join between tables
+ could not horizontally partition + more expensive hash joins

Average

25.7

## Details on All Indexes

A common query pattern:

SELECT store\_name, SUM(revenue)
FROM Facts, Stores
WHERE fact.store\_id = stores.store\_id AND
 stores.country = "Canada"
GROUP BY store name

All qualifying tuples (based on where clause) are selected and reconstructed ("stitched together")

Note that indexes map to TIDs, and then from TIDs we get the column's value

Tuple reconstruction is SLOW!

### Can we simulate a column-store with a row-store?

(a) All Indexes is a poor way to do it

(b) Vertical Partitioning's problem are NOT fundamental

- *i.* tuple header can be removed
- *ii.* TIDs can be virtual
- iii. horizontal partitioning can be based on the values of a different VP

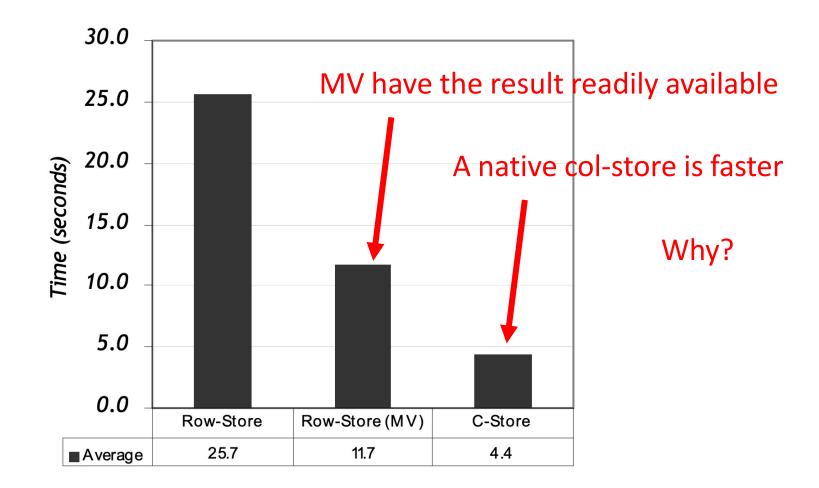

But still, column-stores and row-stores are apples and oranges!!

### Row-Stores vs. Column-Stores (SSB average)

## Methodology

Start from a native column-store

Remove column-store-specific performance optimizations

End with a column-store with a row-oriented query engine

## A. Compression

**Run-length Encoding** 

Q1

Q1

Q1

. . .

Q2

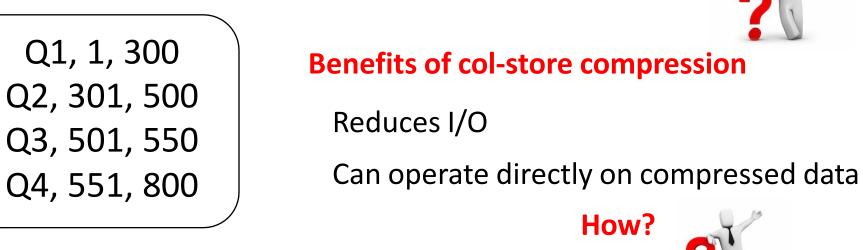

Q2

. . .

#### Alternative: Dictionary Compression

 Replace variable size with minimal fixed length e.g., integer

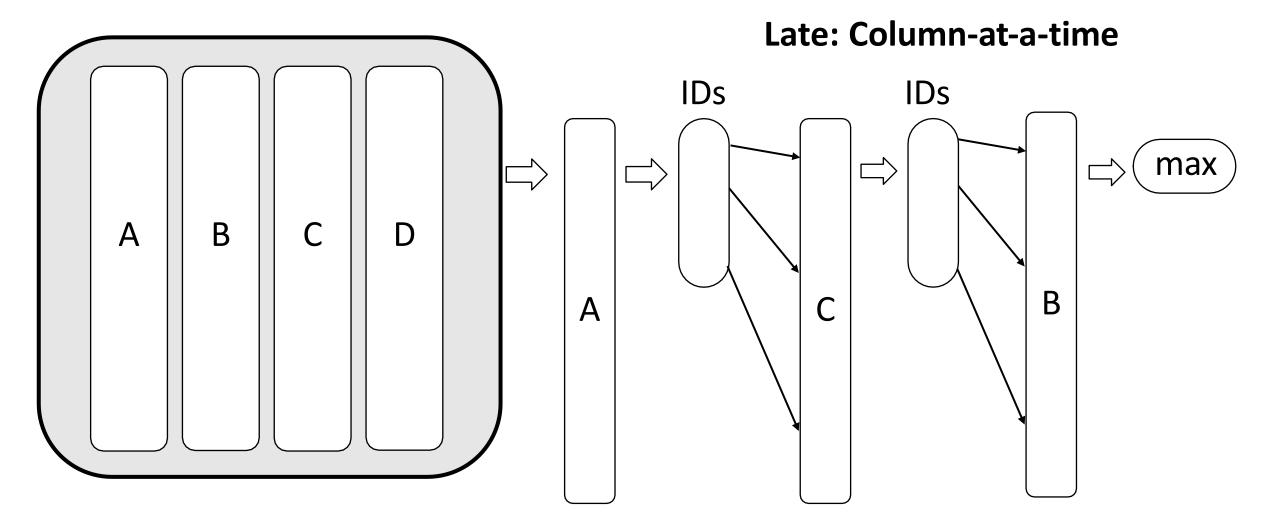

#### Are the same benefits applicable for row-store compression?

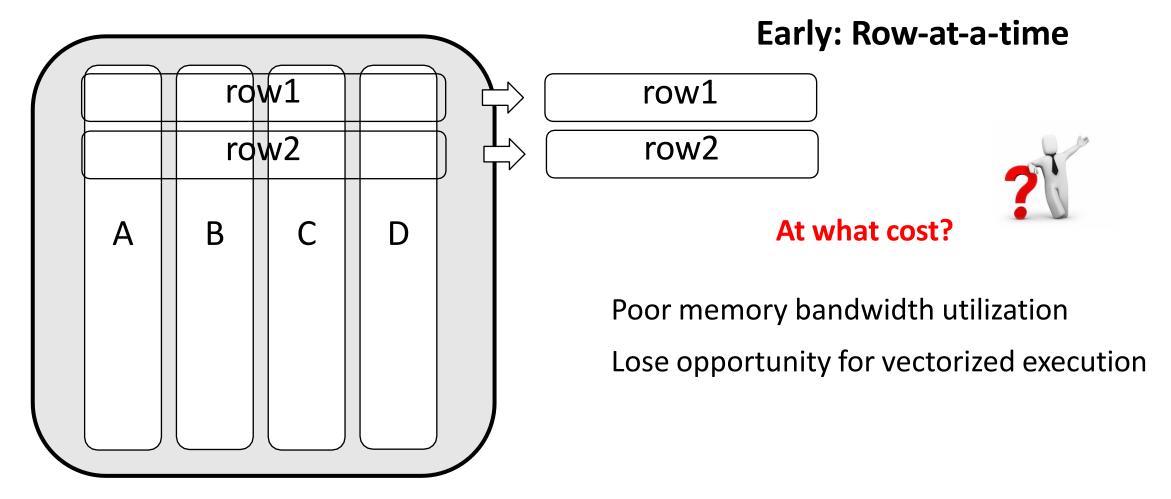

Reduces I/O → yes, but with lower ratio (less data value locality) No! Requires decompression before processing

### B. Early vs. Late Materialization

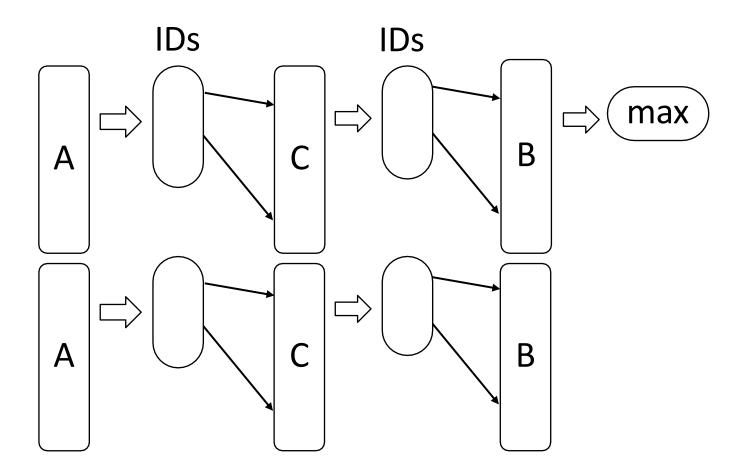

### B. Early vs. Late Materialization

UNIVERSITY OF UTAH

### C. Block Iteration

#### select max(B) from R where A>5 and C<10

#### whole column?

column at a time

block/vector at a time

## D. Invisible Joins

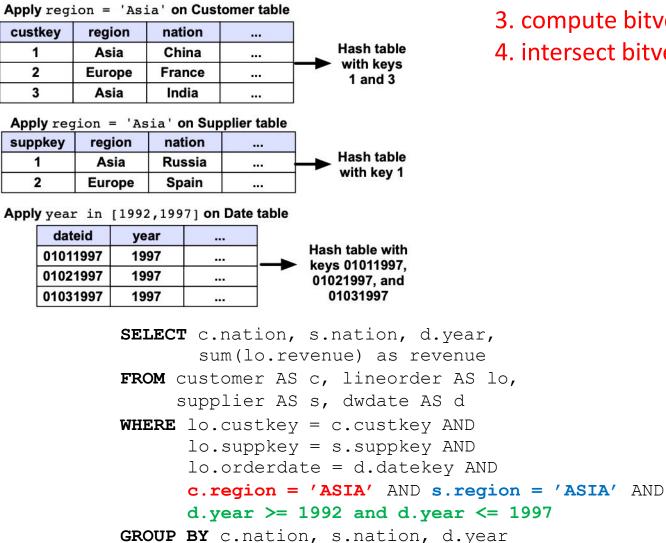

Idea: rewrite joins as predicates on foreign keys in fact table

Algorithm:

- 1. apply each predicate to the appropriate dimension table
- 2. build a hash table on matching keys
- 3. compute bitvector with bits set for qualifying positions (tuples)
- 4. intersect bitvectors (positions) via bitwise AND
- 5. for each resulting position reconstruct the resulting tuple

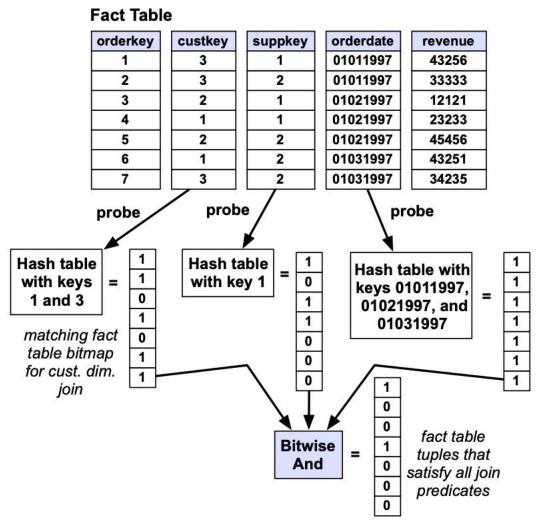

## apply each predicate to the appropriate dimension table build a hash table on matching keys

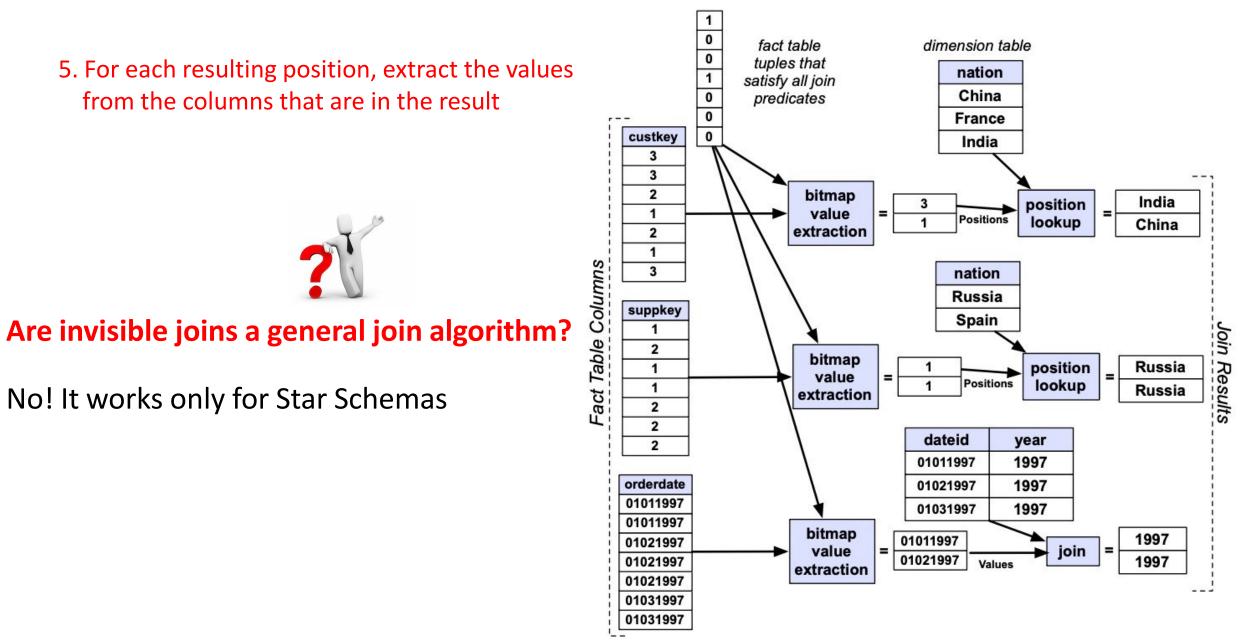

**ORDER BY** d.year asc, revenue desc;

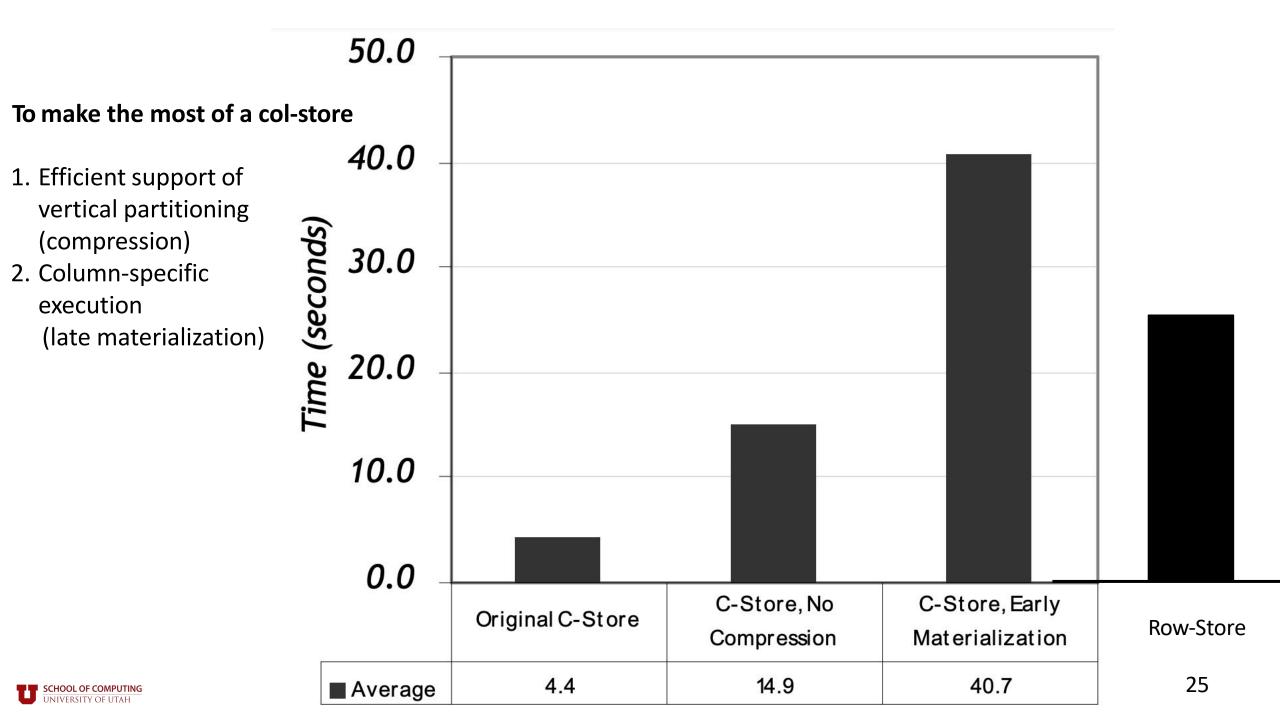

compute bitvector with bits set for qualifying positions (tuples)
 intersect bitvectors (positions) via bitwise AND

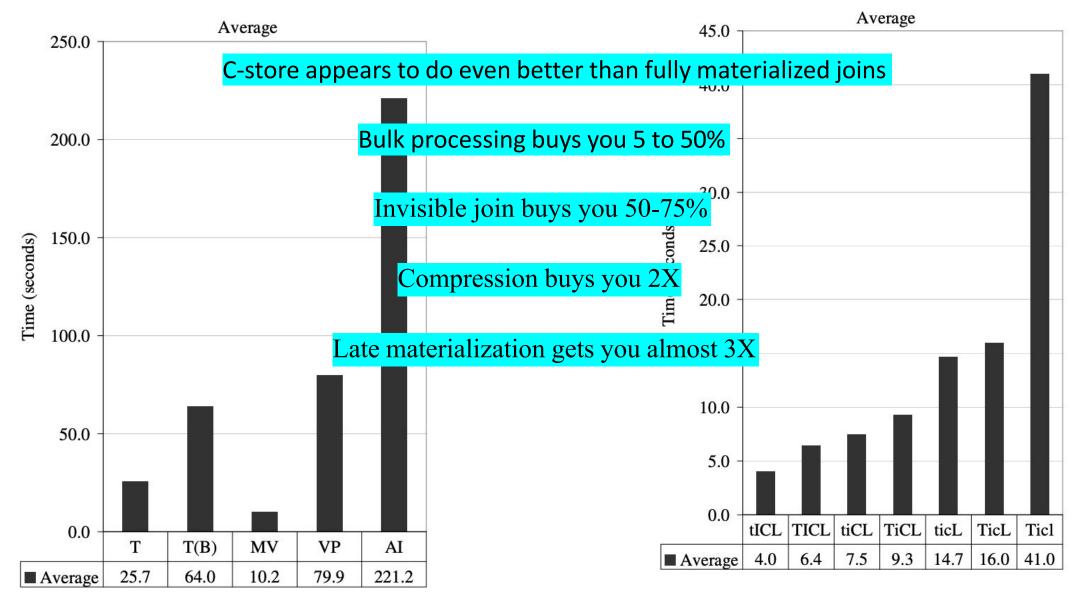

**SCHOOL OF COMPUTING** UNIVERSITY OF UTAH

T is traditional, T(B) is traditional (bitmap), MV is materialized views, VP is vertical partitioning, and AI is all indexes

HOOL OF COMPUTING

T=tuple-at-a-time processing, t=block processing; I=invisible join enabled, i=disabled; C=compression enabled, c=disabled; L=late materialization enabled, l=disabled

## Things to remember

Row-stores vs. Col-stores: fundamental differences

- ✓ Compression
- ✓ Late Materialization
- ✓ Block Iteration
- Column-store-specific join optimizaitons
